

# The QNI Framework

The Quantum-Neuro Interface (QNI) is a theoretical framework proposed by Dr. Aris Thorne in 2045. It bridges the gap between quantum superposition states and human biological neural networks. Unlike traditional BCIs (Brain-Computer Interfaces), the QNI does not rely on electrical impulses measured via EEG or intracranial electrodes. Instead, it utilizes entangled particle pairs to map cognitive intent directly into a digital substrate.

Initial experiments conducted at the Geneva Research Institute demonstrated a 99.8% fidelity rate in translating thought into text, though the system required the user to be immersed in a hyper-cooled quantum stabilization chamber. The primary hurdle remains the decoherence problem: biological systems are inherently noisy and warm, causing the entangled pairs to collapse prematurely.

Dr. Thorne's paper suggests that by introducing a localized Bose-Einstein condensate near the hippocampus, the decoherence time could be extended from milliseconds to several seconds, providing enough window for complex abstract thoughts to be digitized. This marks a significant leap in cognitive augmentation technologies.
